Semiempirical Shell Model Masses with Magic Proton Number Z = 126 for Translead Elements*

S. LIRAN†, A. MARINOV and N. ZELDES
The Racah Institute of Physics, The Hebrew University of Jerusalem, Jerusalem 91904, ISRAEL

A highly extrapolatable semiempirical shell model mass equation applicable to translead elements up to Z = 126 is presented. The equation is applied to the recently discovered superheavy nuclei ^{293}118 and ^{289}114 and their decay products.

I. INTRODUCTION

A recent experiment [1] is consistent with the formation of the nucleus ^{293}118 and its sequential decay down to ^{269}Sg (Z = 106). The α-decay energies vary rather smoothly along the chain, precluding the traditional macroscopic-microscopic [2,3] Z = 114 as a major magic proton number in these nuclei. Recent phenomenological studies of B(E2) [4] and Wigner term [5] systematics indicate Z = 126 as a plausible next spherical proton magic number after lead. Recent self-consistent and relativistic mean field calculations [6–8] variously predict proton magicities for Z = 114, 120, 124 and 126, depending on the interaction used.

Contrary to most of the above findings, the semiempirical shell model mass equation (SSME) [9] is based on the assumption that Z = 114 is the next proton magic number after lead, and it stops there. Moreover, the quality of its agreement with the data starts deteriorating already beyond Hs (Z = 108). (See fig. 1, and fig. 4 of ref. [1].) One has to find a substitute for the equation in the neighbourhood of Z = 114 and beyond.

In the early stages of developing the SSME [10] both Z = 114 and Z = 126, then considered possible alternative candidates for the postlead proton magic number, were tried as an upper shell-boundary for translead elements. The agreement with the data was about the same for both choices, and considering the prevailing view in the mid nineteen-seventies Z = 114 was chosen for the SSME mass table. We have recently [11] established a high predictive power of the early Z = 126 results in the interior of the shell region with Z $\geq$ 82 and 126 $\leq$ N $\leq$ 184 (called here region B) by comparing them to the newer data measured since then, and proposed using them as a substitute for the SSME [9] in superheavy elements (SHE) research. We have also [12] established a high predictive power for Q_α values of the early Z = 126 results in the interior of the shell region with 82 $\leq$ Z, N $\leq$ 126 (called region A). However, the quality of the predicted masses and other mass differences worsened much compared to that of the original adjustment. Therefore we readjusted the coefficients which largely cancel in Q_α, and proposed using the resulting equation as a substitute for the SSME [9] in the interior of region A.

In sect. 2 we give the Z = 126 equation in the two regions and briefly discuss its predictive power. In sect. 3 we apply and comment on it in relation to SHE research in region B.

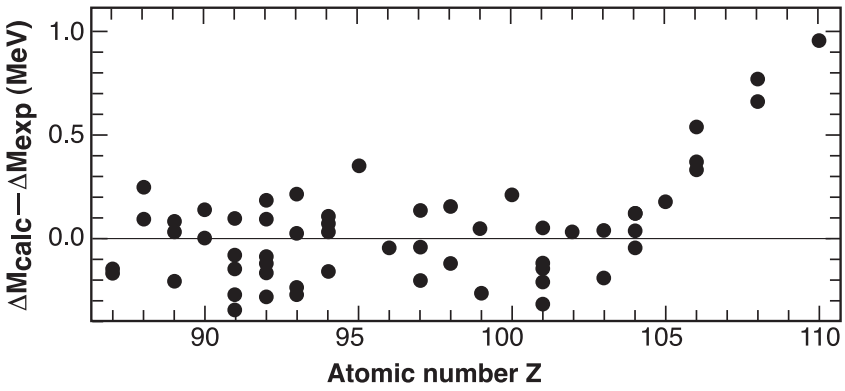

FIG. 1. Deviations of the mass predictions [9] from the data for the 56 new masses in region B measured after the original adjustments were made.

II. THE MASS EQUATION AND ITS EXTRAPOLATABILITY

In the SSME the total nuclear energy E is written [9,13] as a sum of pairing, deformation and Coulomb energies:

$$E\left(N,Z\right)=E_{pair}\left(N,Z\right)+E_{def}\left(N,Z\right)+E_{Coul}\left(N,Z\right)\ , \tag{1}$$

$$E_{Coul}\left(N,Z\right)=\left(\frac{2Z_0}{A}\right)^{1/3}\left[\alpha^C+\beta^C\left(Z-Z_0\right)+\gamma^C\left(Z-Z_0\right)^2\right]\ , \tag{2}$$

$$\begin{aligned}E_{pair}\left(N,Z\right)\ =&\left(\frac{A_0}{A}\right)\left[\alpha+\beta\left(A-A_0\right)+\gamma\left(A-A_0\right)^2+\varepsilon T\left(T+1\right)\right.\\&\left.+\frac{1-\left(-1\right)^A}{2}\Theta+\frac{1-\left(-1\right)^{NZ}}{2}\kappa\right]\end{aligned} \tag{3}$$

for region A, and

$$\begin{aligned}E_{pair}(N,Z)=&\left(\frac{A_0}{A}\right)\left[\alpha+\beta_1(N-N_0)+\beta_2(Z-Z_0)\right.\\&+\gamma_1(N-N_0)^2+\gamma_2(Z-Z_0)^2+\gamma_3(N-N_0)(Z-Z_0)\\&\left.+\frac{1-(-1)^N}{2}\Theta_1+\frac{1-(-1)^Z}{2}\Theta_2+\frac{1-(-1)^{NZ}}{2}\mu\right]\end{aligned} \tag{4}$$

for region B,

$$E_{def}\left(N,Z\right)=\left(\frac{A_0}{A}\right)\left[\varphi_{11}\Phi_{11}\left(N,Z\right)+\psi_{20}\left[\Psi_{20}\left(N,Z\right)+\Psi_{20}\left(Z,N\right)\right]\right] \tag{5}$$

with

$$\Phi_{11}\left(N,Z\right)=\left(N-82\right)\left(126-N\right)\left(Z-82\right)\left(126-Z\right)\ , \tag{6}$$

$$\Psi_{20}\left(N,Z\right)=\left(N-82\right)^{2}\left(126-N\right)^{2}\left(N-104\right) \tag{7}$$

for region A [10], and

$$E_{def}(N,Z)=\left(\frac{A_0}{A}\right)\left[\varphi_{21}\Phi_{21}(N,Z)+\varphi_{31}\Phi_{31}(N,Z)+\chi_{12}X_{12}(N,Z)\right] \tag{8}$$

with

$$\Phi_{21}(N,Z)=(N-126)^2(184-N)^2(Z-82)(126-Z)\ , \tag{9}$$

$$\Phi_{31}(N,Z)=(N-126)^3(184-N)^3(Z-82)(126-Z)\ , \tag{10}$$

$$X_{12}(N,Z)=(N-126)(184-N)(N-155)(Z-82)^2(126-Z)^2(Z-104) \tag{11}$$

for region B [10].

In eqs. (2)−(5) and (8) $A=N+Z$ and $T=|T_z|=\frac{1}{2}|N-Z|$ [‡]. The respective values of (N_0,Z_0,A_0) in regions A and B are (82, 82, 164) and (126, 82, 208). The coefficients multiplying the functions of N and Z are adjustable parameters determined by least squares adjustment to the data, separately for region B [10] and for region A [10,12]. Their values are given in the table.

We discuss extrapolatability first for region B. The experimental data used in the adjustment [10] included 211 masses. Fig. 2 shows the deviations from the data of the predictions of eq. (1) for the 56 presently known new masses measured after the adjustment [10]. The respective average and rms deviations are 53 and 236 keV, as compared to 2 and 126 keV in ref. [10]. The corresponding deviations of Q_α values are −3 and 220 keV, as compared to −6 and 162 keV.

The deviations of the seven N = 126-128 nuclei, denoted by empty circles in the figure, increase when Z increases along the common boundary of regions A and B away from the data. They are related to the increasing discontinuity of the extrapolated mass surface along the common boundary N = 126 of regions A and B away from the data, when the two regions are adjusted separately [9,10]. The deviations of the remaining 49 nuclei with N $\geq$ 129, which do not follow the N = 126 boundary but extend into the interior of the shell region, seem more random and they are smaller, with respective average and rms deviations of −1 and 155 keV.

The above deviations are as a rule about twice smaller than those of several recent mass models. This is presumably due mainly to the inclusion in eq. (1) of the particle-hole $(p-h)$

[‡]In the as yet unknown odd-odd $N=Z$ translead nuclei the ground state (g.s.) is expected to have $T=|T_z|+1$ and seniority zero, whereas eq. (1) with $T=|T_z|$ gives the energy of a low excited seniority two state [13]

symmetric configuration interaction terms E_{def}, eq. (8). A more detailed discussion is given in ref. [11].

TABLE I. Values of the coefficients of eq. (1) determined by adjustment to the data.

Region B [10]		Region A [10,12]	
Coefficient	Value (keV)	Coefficient	Value (keV)
α	-2.3859605×10^6	α	-1.987628×10^6
β_1	-1.496441×10^4	β	-2.4773664×10^4
β_2	-3.3866255×10^4	γ	-8.51085×10^1
γ_1	3.022233×10^1	ε	4.585496×10^2
γ_2	2.811903×10^1	Θ	1.2183×10^3
γ_3	-3.6159266×10^2	κ	2.1937×10^3
Θ_1	8.16×10^2	α^C	7.968418×10^5
Θ_2	1.007×10^3	β^C	2.032906×10^4
μ	-2.121×10^2	γ^C	9.819137×10^1
α^C	8.111517×10^5	φ_{11}	-4.794×10^{-2}
β^C	2.0282913×10^4	ψ_{20}	9.095×10^{-4}
γ^C	1.0930065×10^2		
φ_{21}	-9.87874×10^{-5}		
φ_{31}	3.13824×10^{-8}		
χ_{12}	-1.428529×10^{-7}		

The situation in region A is less simple. The experimental data used in the adjustment [10] included 29 masses and 62 Q_α values connecting unknown masses. The respective average and rms predicted deviations for the presently known 121 new masses which became available after the adjustments increase drastically to −807 and 1008 keV, as compared to −29 and 146 keV in ref. [10]. For the 31 new Q_α values, though, the respective deviations are only 40 and 89 keV, as compared to 5 and 103 keV.

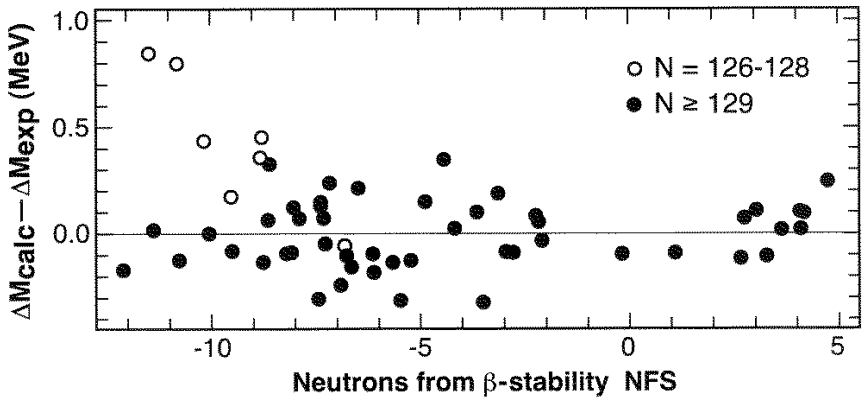

FIG. 2. Deviations of the mass predictions eq. (1) from the data for the 56 new masses in region B measured after the original adjustments were made.

In order to restore to the new mass predictions the same quality as the old predictions had, while at the same time retaining the high quality of Q_α predictions, we made [12] a least-squares adjustment of eq. (1) to all the 150 known masses, with only four adjustable parameters $\alpha, \varepsilon, \Theta$ and κ (eq. (3)) which largely cancel in Q_α, while the other seven coefficients were held fixed on their old values [10]. These are the values given in the table.

The readjusted values of α, Θ and κ are higher and that of ε is lower than in ref. [10], indicating smaller overall binding, smaller symmetry energy coefficient, and increased pairing energies in proton-rich nuclei away from stability.

Fig. 3 shows the deviations from the data of the predictions of the readjusted eq. (1) for all the 150 experimentally known masses. The respective average and rms deviations are 2 and 246 keV. The corresponding deviations of the predicted Q_α values are 2 and 99 keV.

A more detailed discussion is given in ref. [12].

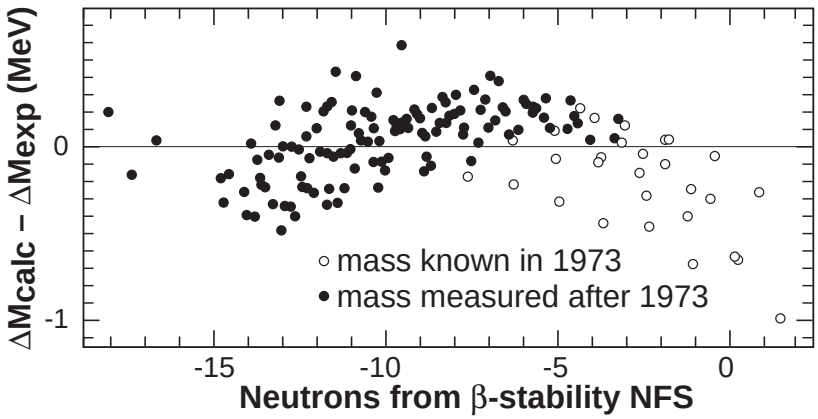

FIG. 3. Deviations of the mass predictions eq. (1) from the data for all the 150 presently known masses in region A.

III. APPLICATIONS TO SHE

Panel a of fig. 4 shows the chain of measured α-decay energies starting from $^{293}118$ [1], and the values predicted for them by eq. (1) when the data are interpreted as g.s. transitions of the assigned nuclei. The figure shows as well the predictions [14] which motivated the search undertaken in [1]. The respective average and rms deviations of the predicted values from the data are -197 and 308 keV for eq. (1) and -154 and 357 keV for ref. [14]. The rms deviation of eq. (1) is consistent with the deviations of the new nuclei in fig. 2 considered above, but the average deviation is too negative. The respective average and rms deviations of the predictions of eq. (1) from those of ref. [14] are -43 and 369 keV.

The variation of the predicted values of eq. (1) along the chain is smoother than that of the data, where there are kinks at Z = 112 and 116 presumably representing submagic numbers or other structure effects. In the SSME such effects are assumed [9,13] to have been smoothed out by configuration interaction, represented by the terms E_{def}. The SSME is inadequate to describe non-smoothed abrupt local changes associated with subshell structure [9].

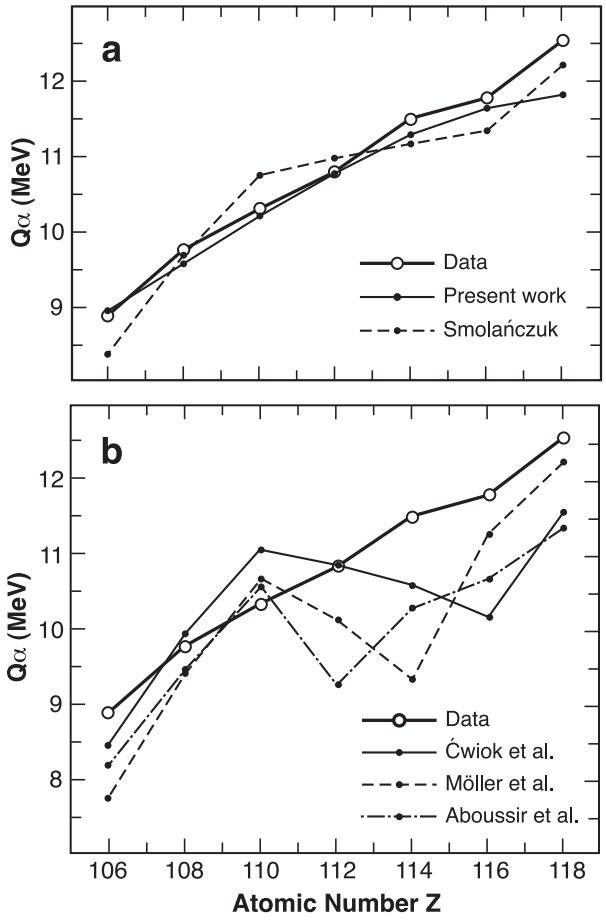

FIG. 4. Experimental [1] and predicted Q_α values of the $^{293}118$ decay chain. (a) Predictions of eq. (1) and of Smolańczuk [14]. (b) Predictions of Ćwiok et al. [15], Möller et al. [16] and Aboussir et al. [17].

On the other hand, the microscopic energies calculated in ref. [14] are basically sums of (bunched minus unbunched) single nucleon energies, and as such have (magic and) submagic gap effects built in. The corresponding predicted line in fig. 4 has kinks at Z = 110 and 116, corresponding to predicted submagic numbers Z = 108 and 116.

Most of the smoothing effect of configuration interaction is missing in macroscopic-microscopic Strutinsky type and in self-consistent mean field calculations. The included $T = 1, J = 0$ pairing correlations seem not to be enough. This might result in calculated submagic gaps and associated kinks which are too large compared to the data. Panel b of fig. 4 shows such predicted large kinks [17,16,15].

As a second application we address the α-decay chain observed in ref. [18], which is considered a good candidate for originating from $^{289}114$ and its sequential decay to $^{285}112$ and $^{281}110$. The respective average and rms deviations of the predictions of eq. (1) from the measured energies are 847 and 905 keV, which considerably exceed the deviations expected from fig. 2 for g.s. transitions. If the above assignments are confirmed, the large deviations might indicate that the decay chain does not go through levels in the vicinity of the g.s.

It might also be worthwhile mentioning, that for the conceivable parents $^{288}112$ or $^{291}113$ which can be obtained from the compound nucleus $^{292}114$ by respective 1α or $1p$ evaporation,

the corresponding average and rms deviations of eq. (1) from the measured energies are −181 and 366 keV and −242 and 417 keV, which are more than twice smaller than for the parent $^{289}114$.

In conclusion we address the bearing of the Z = 118 results on the question of magicity of Z = 126 versus 114. The energy eq. (1) comprises a part $E_{pair} + E_{Coul}$, eqs. (2) and (4), which is a quadratic parity-dependent function of the valence particle numbers, and a part E_{def}, eq. (8), which is a $p - h$ symmetric function of both particle and hole numbers. For different assumed upper shell boundaries the hole numbers are different and E_{def} is a different function of N and Z. The superior agreement of eq. (1) with the data in fig. 4, as compared to the deterioration of the SSME [9] near Z = 114 mentioned in the introduction, demonstrates the superiority of proton-hole numbers defined with respect to Z = 126 as a proton magic number rather than Z = 114. This conclusion has also been arrived at in ref. [4] on the basis of B(E2) systematics. It is important to emphasize, though, that the above rather suggestive results are not a proof of superior magicity of Z = 126 as compared to the recently predicted Z = 120 or 124, because no comparative mass studies of this kind were made.

We thank Stelian Gelberg and Dietmar Kolb for help with the calculations.
